III - BOUNDARY LAYER AND FORCE MEASUREMENTS ON A

SLENDER CONE-CYLINDER BODY OF REVOLUTION

By John R. Jack

SUMMARY

An experimental investigation to determine the aerodynamic characteristics of a slender cone-cylinder body of revolution was conducted in the NACA Lewis 1- by 1-foot supersonic wind tunnel. Viscous drag and three component forces were measured at a Mach number of 3.12 for a Reynolds number range from 2×10^6 to 14×10^6 (based on model length) and for an angle-of-attack range from zero to 9° .

For zero angle of attack, the total-drag coefficient increased with increasing Reynolds number until a Reynolds number of approximately 5.0×10^6 was reached and then remained practically unchanged. A breakdown into components of the total measured drag for a Reynolds number of 14×10^6 and for angle of attack showed that the increment in skin-friction coefficient due to angle of attack was small compared with that of the total-drag coefficient. Theoretical values of the fore-pressure drag, lift, and pitching-moment coefficients obtained from combining a second-order axial-flow solution with a first-order cross-flow solution were calculated for comparison with the experimental results.

INTRODUCTION

As part of a systematic program to ascertain the effects of Reynolds number on aerodynamic characteristics, to extend the basic information on the aerodynamics of bodies of revolution, and to assess the validity of several theories for predicting pressures and forces acting on bodies, tests are being conducted in the NACA Lewis 1- by 1-foot supersonic wind tunnel on a series of bodies of revolution. The first of this series of investigations is reported in reference 1, which contains an appraisal

of the aerodynamics of a near-parabolic nose body. The results of the second investigation are reported in reference 2, which is concerned with the aerodynamic load distributions of a series of five bodies having conical or slightly blunted noses and cylindrical afterbodies. The subject of the present report is the boundary-layer development and forces acting on a typical cone-cylinder body of revolution at a Mach number of 3.12.

The boundary-layer development on the model and the forces acting on the model were determined for a range of Reynolds numbers from 2×10^6 to 14×10^6 (based on body length) and angles of attack from zero to 9° . These data are compared with the compressible boundary-layer theory for cones and with the hybrid theory of reference 3 for the forces.

SYMBOLS

The following symbols are used in this report:

A_F	frontal area
C_D	drag coefficient, $D/q_0 A_F$
C_L	lift coefficient, $L/q_0 A_F$
C_M	pitching-moment coefficient about base of model, $m_p/q_0 A_F l$
C_p	pressure coefficient, $(p-p_0)/q_0$
D	drag
d	maximum body diameter
L	lift force
l	body length
M	Mach number
m_p	pitching moment
p	static pressure
q	dynamic pressure, $(\gamma/2)\rho M^2$
Re	Reynolds number, $\rho U l / \mu$
Re_x	Reynolds number based on length x

- 2738
- U free-stream velocity
 - u velocity in boundary layer
 - x,r,θ cylindrical coordinates
 - α angle of attack
 - γ ratio of specific heats, 1.40
 - δ* displacement thickness, $\frac{1}{\rho_1 u_1} \int_0^{\infty} (\rho_1 u_1 - \rho u) dy$
 - θ momentum thickness, $\frac{1}{\rho_1 u_1^2} \int_0^{\infty} \rho u (u_1 - u) dy$
 - μ viscosity
 - ρ density

- p pressure

APPARATUS AND PROCEDURE

The investigation was conducted in the Lewis 1- by 1-foot variable Reynolds number tunnel, which is a continuous-flow, nonreturn-type tunnel having a test section Mach number of 3.12 ± 0.03. Inlet pressures were varied from 7 to 50 pounds per square inch absolute, and a stagnation temperature of approximately 60° F was maintained throughout the investigation. The entering air had a specific humidity of approximately 2 × 10⁻⁵ pounds of water per pound of dry air, which insured negligible condensation effects.

A schematic diagram with the pertinent dimensions of the pressure-distribution model used to obtain the boundary-layer data is given in figure 1. This model has a nose fineness ratio (l/d) of 6 and an over-all fineness ratio of 12. The boundary-layer data for zero angle of attack were obtained by probing the side ($\theta = 90^\circ$) of the body at six axial stations ($x = 4, 7, 11.8, 14, 17$, and 21 in.) with the probe illustrated in figure 2. The force model was the same as the pressure-distribution model except that it was fabricated from aluminum instead of steel. A three-component strain-gage balance, which was attached to a sting-strut combination, supported the force model. Since the strain gage was mounted internally, no aerodynamic tare corrections were necessary. The maximum experimental errors in the force coefficients are believed to be as follows for the lowest and highest Reynolds numbers, respectively:

Force coefficient	Maximum probable error at Reynolds number, Re	
	2×10^6	14×10^6
C_D	± 0.01	± 0.002
C_L	± 0.02	± 0.002
C_M	± 0.002	± 0.001

Both the pressure-distribution model and the force model were supported from their bases by a sting extending upstream from a horizontal strut mounted to the side wall of the tunnel (fig. 1). In order to obtain minimum interference with the base pressures at zero angle of attack, the sting was designed with the aid of the data presented in reference 4. The model was rotated about a point 4 inches upstream of its base for angle of attack.

REDUCTION OF DATA AND METHODS OF COMPUTATION

The boundary-layer-survey data were evaluated by the Rankine-Hugoniot equation with the assumption that the total temperature was constant in the flow field and that the static pressure was constant along lines normal to the body surface. With these assumptions, velocity profiles were calculated from the known Mach number profiles with the use of the following identity:

$$\frac{u}{u_1} = \frac{M}{M_1} \sqrt{\frac{1 + \frac{\gamma-1}{2} M_1^2}{1 + \frac{\gamma-1}{2} M^2}} \quad (1)$$

From the velocity profiles at the various axial stations, the boundary-layer-displacement and momentum thicknesses may be obtained from

$$\delta^* = \int_0^{\infty} \left(1 - \frac{\rho}{\rho_1} \frac{u}{u_1} \right) dy \quad (2)$$

$$\theta = \int_0^{\infty} \frac{\rho}{\rho_1} \left(\frac{u}{u_1} - \frac{u^2}{u_1^2} \right) dy \quad (3)$$

where $\frac{\rho}{\rho_1} = \frac{1 + \frac{\gamma-1}{2} M^2}{1 + \frac{\gamma-1}{2} M_1^2}$ and y is measured normal to the body surface.

With the displacement and momentum thicknesses known, the mean skin-friction-drag coefficients were then calculated by using the following equation:

$$C_{D,f} = \frac{2\pi}{q_0 A_F} \left[\int_0^s \frac{d(rp_1 u_1^2 \theta)}{ds} ds - \int_0^s r \delta^* \frac{dp}{ds} ds \right] \quad (4)$$

where s represents the distance measured along the body surface. Equation (4) may be derived from the boundary-layer momentum equation for axially symmetric flow with the assumption that the boundary-layer thickness δ is very much less than the body radius (see, for example, ref. 5, pp. 19 and 20). The second term of equation (4) may be neglected since it has been shown that the contribution of the pressure-gradient term to $C_{D,f}$ is very small (see ref. 6).

Theoretical force coefficients for the body at angle of attack were calculated by first obtaining the pressure distributions for the body by the hybrid theory of reference 3 and integrating these numerically to obtain the forces. The hybrid theory of reference 3 is founded on the assumption that the first-order theory of reference 7 yields an adequate cross-flow solution because of the smaller disturbances involved, but a second-order or more exact solution is needed for the axial flow. With the two solutions combined and with the exact isentropic pressure relation used, the pressure coefficient at any point is

$$C_p = \frac{2}{\gamma M_0^2} \left\{ \left[1 + \frac{\gamma-1}{2} M_0^2 \left(1 - \frac{q^2}{u^2} \right) \right]^{\frac{\gamma}{\gamma-1}} - 1 \right\} \quad (5)$$

where

$$\left(\frac{q}{U}\right)^2 = \left(\frac{v_x}{U}\right)^2 + \left(\frac{v_r}{U}\right)^2 + \left(\frac{v_\theta}{U}\right)^2$$

$$\frac{v_x}{U} = \cos \alpha - \phi_{1,x} \sin \alpha \cos \theta + \phi_{2,x} \cos \alpha$$

$$\frac{v_r}{U} = -\sin \alpha \cos \theta - \phi_{1,r} \sin \alpha \cos \theta + \phi_{2,r} \cos \alpha$$

$$\frac{v_\theta}{U} = \sin \alpha \sin \theta + \phi_{1,\theta}/r \sin \alpha \sin \theta$$

ϕ_1 = first-order perturbation potential for cross flow

ϕ_2 = second-order perturbation potential for axial flow

First-order cross-flow terms were calculated by the method of reference 7 and second-order terms were obtained by the method of reference 3. Theoretical force coefficients for the body at angle of attack were also calculated by adding the viscous cross-flow effect to the hybrid theory of reference 3 (see, for example, ref. 3).

RESULTS AND DISCUSSION

Pressure Distributions

For completeness, the pressure distribution at zero angle of attack for Reynolds numbers of 2×10^6 , 8×10^6 , and 14×10^6 obtained from reference 2 are presented in figure 3.¹ Also given in figure 3 are the theoretical curves computed from the second-order theory of reference 3. Agreement between experiment and the second-order theory is very good for the Reynolds number range investigated. Figure 4 shows the variation of base-pressure coefficient with angle of attack for three Reynolds numbers. Detailed pressure-distribution results for this cone-cylinder model at angle of attack and for a range of Reynolds numbers from 2×10^6 to 14×10^6 may be found in reference 2.

¹Because of diffusion of atmospheric air through the flexible plastic tubing used in the manometer system (see ref. 2), pressure distributions presented in reference 2 for the lowest Reynolds number of 2×10^6 were slightly in error. The measurements presented herein were repeated with new model instrumentation and with the diffusion of air into the manometer system practically eliminated.

Boundary Layer

For an experimental correlation of the component drag forces which make up the total drag of the model at zero angle of attack, the movement of transition and total friction-drag coefficients were determined for a range of Reynolds numbers.

The movement of transition was determined with the aid of the schlieren system by taking many microsecond schlieren pictures at the same condition and by averaging the top ($\theta = 180^\circ$) and bottom ($\theta = 0^\circ$) location of the beginning of transition. Figure 5(a) shows the variation of the beginning of transition with free-stream Reynolds number. This curve is very similar to that presented in reference 1 except that it is displaced slightly towards the tip of the model. Figure 5(b) illustrates the behavior of the transition Reynolds number with inlet pressure. Originally this behavior had been attributed to a change in turbulence level or a change in tunnel wall boundary-layer development; however, recently the Naval Ordnance laboratory has obtained similar data in their Pressurized Ballistics Range (ref. 8). Since the turbulence level is small and there is no tunnel boundary layer in this facility, the change in transition Reynolds number with inlet pressure cannot be attributed solely to either of these factors.

The experimental skin-friction-drag coefficients for the six axial stations probed are presented in figure 6 for the range of Reynolds numbers investigated. A comparison of the experimental skin-friction coefficients with the theoretical coefficients obtained from the two-dimensional boundary-layer theories and with those obtained from the transformation presented in reference 9 is also given in figure 5. The basic two-dimensional boundary-layer theories used to make the calculations were the Chapman and Rubesin theory for laminar flows (ref. 10), the extended Frankl and Voishel theory (ref. 11), and the Van Driest theory for turbulent flows (ref. 12). All the above-mentioned theories as used are for flat plates with zero pressure gradients and zero heat transfer. Mangler's derivation (ref. 8) transforms laminar skin-friction coefficients for two-dimensional bodies to those for bodies of revolution with analogous pressure distributions. Since it is shown in reference 6 that the pressure-gradient contribution to the mean skin-friction coefficient is small, the conical transformation is used for comparison; that is,

$$C_{D,f} = \frac{2}{\sqrt{3}} C_{D,f}(\text{flat plate}) \quad (8)$$

The transition data presented in figure 5(a) indicate that the total skin-friction coefficients for the first axial station at each of the free-stream Reynolds numbers investigated should be laminar; yet the three coefficients do not agree with theory. These discrepancies might

be attributed to either (1) errors in measured skin-friction coefficients due to the fact that the ratio of probe height to boundary-layer thickness is not small (ref. 13) or (2) the extreme sensitivity of the velocity profiles on cones to slight misalignments with respect to the stream direction (see, for example, ref. 14). The two points farthest downstream for a free-stream Reynolds number of 4×10^6 are lower than anticipated (fig. 6) in view of the fact that the transition data of figure 5(a) obtained at the top and bottom of the body indicate that these should be in the transition region or beyond. A possible explanation of this behavior may be that the transition point on the side of the body ($\theta = 90^\circ$) where the boundary layer was probed does not coincide with the transition point obtained from the top and bottom surfaces of the body. The fact that the axial location of transition may vary around a cone-cylinder body of revolution is illustrated in reference 9, in which this distribution was obtained utilizing the luminescent lacquer technique.

After passing through transition, the experimental skin-friction coefficients tend to approach a maximum and then decrease at a rate much greater than that predicted by either the theory of reference 11 or of reference 12. Except for the possibility of the transition point moving with time, no reason for this behavior can be given; however, this same behavior pattern was noted in reference 1 for a body of revolution having a near-parabolic forebody and a cylindrical afterbody. In view of the preceding discussion, and since the turbulent boundary-layer theory has not been corrected either for the initial laminar boundary layer or for the difference between two-dimensional and axially symmetric flow, no definite conclusions can be made regarding the comparison between experimental and theoretical turbulent skin-friction coefficients. The displacement and momentum thicknesses from which the mean skin-friction coefficients presented in figure 6 were obtained are given in figure 7.

Forces

The experimental variation of total-drag coefficient with Reynolds number for zero angle of attack is presented in figure 8. The drag coefficient increased with increasing Reynolds number until a Reynolds number of approximately 5.0×10^6 was reached and then remained relatively constant. The contributions to the total-drag coefficient of fore-pressure, base-pressure, and skin-friction-drag coefficients as measured on the pressure-distribution model are also presented. As seen, the summation of the drag components closely approximates the total measured by a strain-gage balance. A similar variation of total-drag coefficient with Reynolds number is observed in reference 1. None of the variation of the total-drag coefficients with Reynolds number is due to a change in the fore-pressure-drag coefficient.

973R
The effect of angle of attack on the total-drag coefficient is given in figure 9 for three Reynolds numbers. For the lower angles of attack, the drag coefficient increased with increasing Reynolds number up to a Reynolds number of approximately 8×10^6 and then remained relatively constant. At angles of attack greater than 6° , the drag coefficient increased continuously with Reynolds number for the Reynolds number range investigated.

In evaluating performance characteristics of supersonic missiles, the variation of total drag with angle of attack is quite important and, consequently, the variation of friction drag with angle of attack becomes significant since it can contribute as much as 50 percent to the total drag. Therefore, in order to give an insight into this behavior, the fore-pressure- and base-pressure-drag coefficients for a Reynolds number of 14×10^6 have been subtracted from the total-drag coefficient to give the variation of skin-friction coefficient with angle of attack (fig. 10). This has been done for a Reynolds number of 14×10^6 since the higher Reynolds numbers are of more practical concern. It must be pointed out, however, that the variation of skin-friction coefficient with angle of attack is only qualitative since this calculation involved a numerical integration to obtain the fore-pressure-drag coefficient and, consequently, may be in error. Figure 10 does indicate, however, that the variation of the increment in skin friction due to angle of attack is small compared with the total-drag increment.

Also presented in figure 10(a) is a comparison between the pressure-drag increment due to angle of attack and the theory of reference 3. This comparison shows that the theory of reference 3 is in good agreement with experiment up to an angle of attack of 6° , but from 6° to 9° the theory predicts values much too low. The lack of agreement at the high angles of attack appears to be due to effects not considered in the potential equation, namely, the viscous cross-flow effects. By adding the viscous cross-flow effects as suggested in reference 3 to the potential theory of reference 3, the increment in experimental fore-pressure drag due to angle of attack is predicted closely (fig. 10(b)).

Experimental results showing the variation of lift coefficient with angle of attack are compared with the hybrid theory of reference 3 in figure 11. Agreement between experiment and theory is fair up to a 3° angle of attack, but the predictions of the theory for the higher angles of attack are quite low. Again, adding the viscous effect to the theory of reference 3 brings the theoretical lift variation into fair agreement with experiment.

The experimental variation of the pitching-moment coefficient about the base of the model and the center of pressure are given in figures 12 and 13, respectively. The trends of the experimental pitching moment and center of pressure with angle of attack are predicted by the theory of

reference 3 with the addition of the viscous cross-flow effect. The magnitude of the experimental values of the pitching moment and the center of pressure is, however, higher than would be predicted by theory. As in the case of the lift coefficient, the effect of Reynolds number is small.

SUMMARY OF RESULTS

The aerodynamic characteristics of a slender cone-cylinder body of revolution were investigated in the NACA Lewis 1- by 1-foot variable Reynolds number tunnel at a Mach number of 3.12. The results may be summarized as follows:

1. The total-drag coefficient for zero angle of attack increased with increasing Reynolds number until a Reynolds number of approximately 5.0×10^6 was reached and then remained relatively constant.
2. A breakdown of the total measured drag into components for a Reynolds number of 14×10^6 and for angle of attack showed that the increment in skin-friction-drag coefficient due to angle of attack was small compared with that of the total-drag coefficient.
3. Experimentally measured drag and lift were in good agreement with Van Dykes' hybrid theory at small angles of attack. By adding the viscous cross-flow effect to the hybrid theory, much better agreement between experiment and theory was obtained for all angles of attack.
4. The trends of the experimental pitching moment and center of pressure with angle of attack are predicted by Van Dykes' hybrid theory with the addition of the viscous cross-flow effect; however, the magnitude of the experimental values was higher than the theory would predict.
